Mtor-Fanconi Anemia DNA Damage Repair Pathway in Cancer

Keywords: mTOR; Fanconi anemia pathway; FANC2; DNA repair; Tumorigenesis; Drug resistance; mTOR targeting

Abstract

mTOR is a serine/threonine kinase and plays a critical role in mammalian cell growth, survival, and metabolism. mTOR is present in two cellular complexes: mTORC1 and mTORC2. Dysregulation of the mTOR pathway has been related to tumorigenesis, poor prognosis of/ or chemotherapy resistance in a variety of malignancies. Inhibition of mTORC1 by Rapamycin and its analogs has been explored to treat a number of tumors. However, the effectiveness of patient response is limited and not all patients respond. Second generation of mTOR inhibitors have recently been developed to target mTOR kinase activity and to suppress both mTORC1 and mTORC2. Dual mTORC1/mTORC2 inhibitors generally are more efficacious in preclinical studies and clinical trials. We and others have recently found that dual mTORC1/mTORC2 inhibitors sensitize T-cell acute lymphocytic leukemia and rhabdomyosarcoma cells to DNA damaging agents by suppression of expression of FANC2 of the Fanconi anemia pathway, an important DNA repair mechanism that is associated with drug resistance of multiple types of cancer. This review will highlight mTOR and the Fanconi anemia pathway in cancer, with a particular attention to our newly discovered connection between mTOR and the Fanconi anemia pathway.

Introduction

The mammalian target of Rapamycin (mTOR) is a serine/threonine kinase that signals through two parallel molecular complexes: mTORC1 and mTORC2 [1]. mTORC1 contains Raptor, mLST8, PRAS40 and Deptor, while mTORC2 contains Rictor, mLST8, mSin1 and Protor [1]. In response to nutrients, growth factors, and intracellular energy status, mTORC1 is activated by signaling through phosphatidylinositol-3-OH kinase (PI3K), PKD1 and Akt [2]. mTORC1 activation leads to phosphorylation of the translational regulators S6K1 and 4E-BP to regulate protein synthesis, cell growth and metabolism. mTORC2, on the other hand, can regulate cell survival via phosphorylating Akt on Ser473 [2,3]. The critical role of mTOR is attested by the lethality of mice harboring full-body knockout of mTOR and by tissue-specific knockout of mTOR complex components [4-24].

mTOR has been suggested to regulate DNA damage response (DDR) that is important for maintenance of genomic stability [25-27]. Mammalian cells have evolved a complex network of DDR to sense and respond to genotoxic agents [28]. Activation of DDR leads to the repair of DNA damage and genomic restoration, with cell death being an alternative outcome [29]. A major DDR network consists of Fanconi anemia (FA) DNA repair pathway; mutation of each of the 15 known FANC genes causes FA syndrome in human, which is often manifested by bone marrow failure [30-32].

This brief review will outline mTOR and the FA pathway in cancer, with a particular attention to our newly discovered connection between mTOR and the FA pathway.

mTOR in cancer

mTOR plays a crucial role in regulating cancer cell growth, proliferation, survival, migration and tumor angiogenesis [33]. Hyperactivation of mTOR signaling has been reported in many cancers (e.g. renal cell carcinoma, chronic myeloid leukemia) [34,35]. Deregulation of mTOR signaling in cancer occurs through complex mechanisms, including overexpression or activation of oncogenic Ras, PI3K, Akt, epidermal growth factor receptor (EGFR), BCR-ABL or loss of function of tumor suppressor genes phosphatase and tensin homolog (PTEN), tuberous sclerosis complex (TSC), and LKB1 [35-37]. mTOR downstream targets are also deregulated in a number of tumors. For example, S6K1 overexpression or activation has been detected in several cancer cell lines including breast cancer cells [33,34]. It has been shown that 4E-BP1 is overexpressed in gastrointestinal cancer and is hyperactivated in breast cancer and ovarian tumors [33].

Deregulation of mTOR pathway has also been implicated in chemotherapy resistance mechanisms. Overexpression of mTOR and S6K1 has been associated with TRAIL resistance of glioblastoma [38]. The resistance of NB4 promyelocytic cells to retinoic acid is related to defects in the regulation of 4E-BP1 and 4E-BP2 [39]. mTOR activation is linked to vincristine resistance of pro-B lymphoma cells [40]. Activation of mTOR and S6K1 is indicated in cisplatin or Adriamycin resistance of hepatocellular carcinoma, lung carcinoma, T-cell acute lymphocytic leukemia (T-ALL), and fibrosarcoma cells [41]. In addition, the aberrant activation of mTOR signaling has been detected in chemo-, radio- and/or hormone-resistant chordoma, breast cancer, pancreatic cancer, and prostate cancer cells [42-45].

Because of its pivotal role in tumorigenesis and drug resistance, mTOR has presented itself as a valid target for the treatment of...
various cancers. Targeting mTORC1 by rapamycin and its analogs has been explored in preclinical studies and clinical trials to treat tumors of diverse cellular origin. A rapamycin analog Temsirolimus was approved for treating renal cell carcinoma by the US Food and Drug Administration (FDA) in 2007. However, in general the length of patient response to rapamycin or rapamycin analogs is limited and not all patients respond. This could be attributable to several factors.

First, rapamycin and its analogs release the negative feedback loop between S6K and Akt, resulting in Akt hyperactivation. Second, rapamycin and its analogs can only transiently inhibit the activity of 4E-BP1, leading to suboptimal inhibition of protein synthesis. Finally, rapamycin and its analogs have minimum inhibitory effect on mTORC2 activity [36,37,46,47]. It is noted that mTORC1 and mTORC2 may be complementary to each other in regulating cellular functions with mTORC1 governing cell growth, proliferation and metabolism, while mTORC2 regulating cell survival [2,3]. That said, it is unlikely that mTORC1 inhibitors suppress cell survival. Even worse, mTORC1 inhibitors may enhance cell survival through Akt activation that is known to be regulated by mTORC2 [2,3], and therefore, reminiscent of compensatory increase of mTORC2 activity.

To overcome the limitations of mTORC1 inhibitors, a new generation of mTOR inhibitors has recently been developed to target mTOR kinase activity and thus both mTORC1 and mTORC2. Compared to rapamycin and its analogs, these dual mTORC1/mTORC2 inhibitors, overall, have significantly higher anticancer efficacy. Among them, AZD8055, OSI-027 and INK128 have entered into clinical trials [35]. Readers are referred to a number of excellent reviews on this topic published recently [34,47-49]. It is notable that dual mTORC1/mTORC2 inhibitors may also be more effective than rapamycin and its analogs in combinatorial therapy. For example, a dual mTORC1/mTORC2 inhibitor pp242 synergized with bortezomib in inhibition of multiple myeloma (MM) cell growth and survival, whereas this synergistic effect was not seen when the cells were treated with rapamycin in combination with bortezomib [50,51]. An important issue concerning dual mTORC1/mTORC2 inhibitors is that they may activate ERK/MAPK pathway [50,52], leading to cancer cell hyperproliferation. However, this is likely a cell type-specific event. While MM cells treated with pp242 showed an increased ERK phosphorylation [50,52], we observed an attenuated ERK activation in pp242-treated T-ALL cells [53]. Another caveat is that dual mTORC1/mTORC2 inhibitors may induce autophagy, which could promote cancer cell survival [49]. These drawbacks may be circumvented by combining dual mTORC1/mTORC2 inhibitor with ERK inhibitor or autophagy inhibitor. Indeed, even mTORC1 inhibitor can synergize with autophagy inhibitor in inhibition of endothelial cell growth [54].

The FA DNA repair pathway in cancer

The FA signaling pathway is essential for DNA damage repair and thus for maintaining genomic stability. Upon DNA damage, the FA core complex containing FANCA and FANCFC, among others, induces monoubiquitination of FANCD2, which in turn leads to FANCD2 translocation to nuclear foci and subsequent DNA repair [31,55]. Mutation or silencing of genes controlling the FA pathway causes a genomic instability syndrome, namely FA, that is defective for DDR resulting in cellular hypersensitivity to DNA damaging agents [30].

Gain-of-function in the FA pathway (e.g. overexpression of FA proteins) appears to play a key role in underlying drug resistance of multiple types of cancer. The FA pathway has been identified as a key pathway in both chemo- and radio-resistance of mesothelioma [56]. FANCF and FANCDD2 contribute to melphalan resistance of MM cells [57-59]. DNA alkylating agent resistance of glioma and cisplatin resistance of ovarian cell cells are attributable to increased FANCD2 monoubiquitination and FANCDD2 nuclear foci formation [60,61]. In head and neck cancer cells, proficient FANCDD2 foci formation is associated with cisplatin resistance [62]. In addition, FANCDD2 is related to etoposide resistance of lung cancer cells and doxorubicin resistance of breast cancer cells [63]. Thus, it has been a long sought-after goal in the FA field that rational targeting the FA pathway may provide a chemo-sensitizing avenue for more effective DNA damaging chemotherapy [63-67].

Linkage of mTOR to the FA pathway

mTOR is known to regulate DDR [25,26]. By gene targeting approach, we have recently shown that deletion of mTOR in mouse hematopoietic stem and progenitor cells causes a defective DDR to a variety of DNA damage agents (e.g. melphalan, mitomycin C, γ-ionizing radiation) [68]. Mechanistically, we demonstrate that mTOR deficiency decreases expression of FANCDD2 [68]. This regulation of FANCDD2 expression by mTOR is conserved in mouse myeloid cells and human B lymphoblasts, because ablation of mTOR in mouse myeloid cells or inhibition of mTOR in human B lymphoblast by dual mTORC1/mTORC2 inhibitors (e.g. pp242, Torin 1) suppresses FANCDD2 expression [53,68]. We further show that mTOR deficiency or inhibition increases phosphorylation and nuclear translocation of nuclear factor (NF)-κB, which results in an enhanced NF-κB binding to FANCDD2 promoter to suppress FANCDD2 expression [68]. It appears that mTOR negatively regulates NF-κB activity by direct binding to IKK and that mTOR knockout or inhibition disrupts the mTOR-IKK complex to release IKK for binding to and activation by TAK1 leading to increased NF-κB nuclear activity [68] (Figure 1A). Interestingly, mTOR-NF-κB-FANCDD2 signaling circuitry seems not to be dependent on mTORC1 or mTORC2, because deletion of either the mTORC1 component Raptor or the mTORC2 component Rictor has no effect on FANCDD2 expression [68].

We have also found that mTOR-NF-κB-FANCDD2 signaling hub exists in human T-ALL cells [53]. However, in T-ALL cells, the downregulation of FANCDD2 by mTOR inhibition correlates with a deactivation of NF-κB (our unpublished data), suggesting that NF-κB plays a positive role in mediating FANCDD2 expression in these cells, reminiscent of that in melphalan-resistant MM cells [59] (Figure 1B). In line with our discovery, mTOR has been found to regulate FANCDD2 expression in rhabdomyosarcoma cells [69], particularly in alveolar rhabdomyosarcoma harboring the PAX3/FOXO1 fusion gene [70]. It is worth noting that in T-ALL cells, we did not detect an inhibitory effect of rapamycin on FANCDD2 expression, consistent with the mTORC1-independent role of mTOR in the regulation of FANCDD2 expression in mouse hematopoietic stem and progenitor cells. However, in rhabdomyosarcoma cells,
it appears that mTORC1 accounts for mTOR effect on FANCD2 expression [69]. Thus, whether mTOR regulates FANCD2 expression through mTORC1 is contingent on cell types. Interestingly, suppression of FANCD2 expression by mTOR inhibition deactivates DNA damage sensors ATM and ATR kinases [69]. Thus, mTOR may mediate DDR through governing FANCD2 expression and subsequent activation of ATM-Chk2 and ATR-Chk1 pathways that otherwise have been suggested to activate the FA core complex and to facilitate FANCD2 translocation to nuclear foci [55,71] (Figure 2). These recent findings raise the prospect of using mTOR inhibitors, particularly dual mTORC1 and mTORC2 inhibitors, in combination with DNA damaging chemotherapy as a potential future approach for the treatment of cancers. Indeed, we show that dual mTORC1 and mTORC2 inhibitor pp242, AZD8055, or INK128, but not rapamycin, sensitizes T-ALL cells for AraC-, etoposide- and tofacitinib-induced DNA damage and apoptosis. Accordingly, the combinatory treatment significantly prolongs lifespan of T-ALL cell line- or patient cell-xenografted mice [53].

**Conclusion and Prospective**

While targeting mTOR is promising for cancer treatment, inhibition of mTORC1 by rapamycin or its analogues has limited clinical efficacy. The development of more potent dual mTORC1/ mTORC2 inhibitors represents a major advance in mTOR targeting. However, because dual mTORC1/mTORC2 inhibitors work by competing with ATP to bind to mTOR kinase domain, they may elicit off-target effects on related kinases and thus not be as specific as rapamycin and its analogues [47]. Nonetheless, dual mTORC1/ mTORC2 inhibitors work well and are well tolerated in a xenograft study of prostate cancer [72]. We have also shown that there is a therapeutic window that combined dual mTORC1/mTORC2 inhibitor pp242 with AraC can significantly extend life span of mouse xenografts of T-ALL [53]. Nevertheless, any clinical benefit of dual mTORC1/mTORC2 inhibitors needs to be weighed against their greater toxicity in comparison with rapamycin and its analogues.

mTOR plays a critical role in anti-cancer drug resistance. The molecular mechanism of mTOR underlying drug resistance remains poorly studied. With that FANCD2 monoubiquitination and FANCD2 nuclear foci formation have been shown to be prognostic in drug resistance [60,61], we and others suggest that greater FANCD2 transcript and protein levels may underlie mTOR-regulated drug resistance [53,69,70]. A correlation of mTOR-associated genes with FANCD2 gene expression has been demonstrated in alveolar rhabdomyosarcoma patients [70]. Thus, FANCD2 transcript and protein contents could potentially serve as a predictive biomarker for responsiveness of drug-resistant cancer patients to mTOR inhibition. That is to say, targeting mTOR-FANCD2 pathway by using dual mTORC1/mTORC2 inhibitors may represent a novel and selective sensitizing strategy to combat drug resistance of cancer patients to other anticancer agents, particularly DNA damaging agents. The identification of FANCD2 as a biomarker of mTOR targeting responsiveness is apparently beneficial for patient stratification and eventual clinical success of mTOR inhibition. However, it should be realized that mTOR-FANCD2 signing node also exists in normal cells [68]. Thus, targeting this pathway may yield severe side effects, for instance, bone marrow failure that is seen in FA patients harboring mutation or deficiency in the FA pathway [32]. Of note, in the context of mTOR signaling, FANCD2 expression is differentially regulated by NF-κB in normal cells versus cancer cells. In normal cells (e.g. mouse hematopoietic stem and progenitor cells, human B lymphoblasts, mouse embryonic fibroblasts), we show that mTOR inhibition leads to an increased NF-κB activation, which in turn suppresses FANCD2 expression [68], whereas in cancer cells (e.g. T-ALL), mTOR inhibition leads to a decreased NF-κB activation and FANCD2 expression [53] (our unpublished data). Therefore, if severe side effects arise, we might adopt a salvage protocol by further addition of NF-κB inhibitor to alleviate cytotoxicity in normal cells.
