Regulation of Adherens Junctions in Trabecular Meshwork Cells by Rac GTPase and their influence on Intraocular Pressure

Keywords: Rac GTPase; Adherens junctions; Cytoskeleton; Trabecular meshwork; ROS; Intraocular pressure

Abstract

Intercellular adherens junctions and cell-extracellular matrix interactions are presumed to influence aqueous humor (AH) drainage via the conventional route, however, their direct role in modulation of intraocular pressure (IOP) is not well understood. Here, we investigated the role of Rac GTPase signaling in basal and growth factor-induced formation of adherens junctions in human trabecular meshwork (HTM) cells as compared to human umbilical vascular endothelial cells, and evaluated the effects of inhibition of Rac GTPase activity on IOP in rabbits. Expression of a constitutively active Rac1 GTPase or treatment with platelet derived growth factor (PDGF), a known activator of Rac GTPase, induced formation of β-catenin-based adherens junctions, actin cytoskeletal reorganization and membrane ruffle in HTM cells. In contrast, treatment of HTM cells with inhibitors of Rac GTPase caused cell-cell separation, a decrease in adherens junctions, and reorganization of actin stress fibers to the cell cortical regions and focal adhesion to the cell leading edges. Both, constitutively active Rac1 and PDGF stimulated generation of Reactive Oxygen Species (ROS) in HTM cells, and ROS were found to increase adherens junction formation and transendothelial electrical resistance (TEER) in HTM cells. Topical application of Rac GTPase inhibitors (EHT1864 and NSC23766), however, only marginally influenced IOP in rabbit eyes. Taken together, these data reveal that while Rac GTPase signaling plays a significant role in regulation of adherens junctions, ROS production and TEER in cells of the AH outflow pathway, Rac inhibitors showed only a marginal influence on IOP in live rabbits.

Introduction

Glaucoma is the second leading cause of blindness in the United States. A major risk factor for primary open-angle glaucoma is elevated intraocular pressure (IOP) caused by increased resistance to aqueous humor (AH) outflow localized within the conventional/trabecular pathway [1-3]. Dysregulated transendothelial permeability barrier activity of Schlemm’s canal stemming from altered cell-cell and cell-extracellular matrix (ECM) interactions is presumed to be partly responsible for increased resistance to drainage of AH through the conventional pathway [4-8]. Extracellular cues such as growth factors, ECM and steroids are thought to influence AH outflow resistance via altering the cytoskeletal organization, contractile properties, cell-cell junctions, cell-ECM interactions and permeability barrier of cells within the AH outflow pathway [4,7-9,15]. The mechanistic basis by which cell-cell junctions in AH outflow pathway are regulated, and the direct role of these complexes in AH drainage and IOP homeostasis, however, has remained elusive. Therefore, studies to address the formation and regulation of the adherens junctions, which represent a predominant type of cell-cell junction in endothelia [16], seem both necessary and critical for exploring a potential role for these junctions in IOP homeostasis. This knowledge may provide important insights into the etiology of glaucoma and support development of novel therapies.

The conventional AH drainage pathway consists of the trabecular meshwork (TM), juxtacanalicular tissue (JCT) and Schlemm’s canal (SC) [3]. The TM is a filter made up of collagen-based connective tissue organized into a network of beams covered by endothelial-like trabecular cells. As AH moves from the TM to the JCT adjacent to the inner wall of SC, the spaces between the beams decrease [3,17]. Although the maximal resistance to AH outflow is thought to occur at the junction where the TM meets the inner wall of SC [17,18], it is also commonly believed that the TM, SC and JCT contribute to resistance to AH drainage via maintenance of normal cell shape, cell-cell junctions and cell-ECM interactions, which subsequently influence permeability barrier integrity and tissue stiffness, analogous to what occurs in the vascular endothelium [12,18,19-21]. Further, it is well documented that the cells of the conventional outflow pathway possess endothelial-like properties [20,22]. The endothelium acts as a semi-permeable barrier and regulates fluid and solute exchange in many different tissue types [23-25]. Permeability of endothelial cells is determined by the adhesive properties of the proteins that comprise the tight junctions and adherens junctions [24-28].

Currently there are a few published studies of the AH outflow pathway that directly address the importance of cell-cell junctions and their role in modulation of AH drainage and IOP [4,6,7,14,15,21,29]. Syriani et al. [30] recently reported that perfusion of PDGF through enucleated bovine eyes increases AH outflow facility likely through the stimulation of Rac GTPase activity and altered cytoarchitecture and cell-cell junctions in cells of the outflow pathway. However, other agents which are known to activate Rac GTPase activity and stimulate cell-cell junction formation including Sphingosine-1-phosphate, have been shown to decrease AH outflow facility in perfused model systems possibly via increased transendothelial permeability barrier of SC [7,10,31]. However, in these latter studies, the direct role of Rac GTPase activity in either cell-cell junction formation or on IOP has not been addressed.

The Rho GTPases including Rac and Rho, have been demonstrated to regulate transendothelial permeability barrier by controlling actin...
cytoskeletal reorganization, contractile properties, cell-cell junctions and cell-ECM interactions in different cell types [26,28,32]. Moreover, the aberrant activity of Rho GTPases underlying impaired permeability barrier function in endothelial cells is known to be involved in various pathological conditions [24,33,34]. Various growth factors, mechanical stress and oxidative stress are also recognized to influence activity of the Rho GTPases and transendothelial permeability [24,28,29,35]. Therefore, in this study, we evaluated the direct effects of Rac GTPase activation and inactivation on adherens junctions formation in HTM cells as compared to human umbilical vascular endothelial cells (HUVEC) used as a model SC endothelial cell type, and on IOP changes in a live animal model.

Materials and Methods

Reagents

Two different Rac inhibitors- N6-[2-[[4-(Diethylamino)-1-methylbutyl]amino]-6-methyl-4-pyrindinyl]-2-methyl-4,6-quinolinediamine trihydrochloride and EHT1864 (5S-5S-[7-[7-[4-((Trifluoromethyl)quinolin-4-ylthio)pentyl]oxy]-2-(morpholinomethyl)-4H-pyran-4-one dihydrochloride) that inhibit either Rac GTPase interaction with guanosine nucleotide exchange factors [36] or Rac GTPase activation [37,38], respectively, were purchased from Tocris Biosciences (Ellisville, MO) and Sigma-Aldrich (St. Louis, MO), respectively. Rho kinase inhibitor (Y27632) was provided by Welfide Corp (Tokyo, Japan). Human recombinant PDGF AA (CYT-341) was purchased from Prospec (Israel). N-acetyl-L-cysteine (A7250), hydrogen peroxide solution (H1009), diphenyleinodionium chloride (D2926), mouse monoclonal anti-vinculin (V4505), anti-tubulin (B5168), anti-β-catenin (C7207), rhodamine conjugated phalloidin and FITC conjugated anti-vinculin (V4505), anti-tubulin (B5168), anti-β-catenin (C7207), rhodamine conjugated phalloidin and FITC conjugated phalloidin were purchased from Sigma-Aldrich (St. Louis, MO). 2′,7′-dichlorodihydrofluorescein diacetate was purchased from Invitrogen (Grand Island, NY).

Mouse monoclonal anti-V-VE-Cadherin antibody (MAB1989) was procured from EMD Millipore (Billerica, MA). Phospho-myosin light chain antibody (36745) was from Cell Signalling Technology (Danvers, MA).

HTM and HUVEC cell cultures

Human TM (HTM) cells were cultured from the TM tissue derived from donor eyes (obtained from local eye banks) as we described earlier [39]. Cell cultures were maintained in Dulbecco’s modified Eagle’s medium (DMEM) containing 10% fetal bovine serum (FBS) and penicillin (100 U/500 ml)-streptomycin (100 mg/500 ml)-glutamine (4 mM). Human umbilical vascular endothelial cell line (HUVEC) purchased from Clonetics (San Diego, CA) was cultured in EGM-2 (Endothelial Growth Medium) medium supplemented with FBS, hydrocortisone, rhEGF, bovine brain extract and antibodies (Gentamicin sulphate and Amphotericin-B) as per the manufacturer’s instructions (Clonetics). All cells were cultured at 37°C under 5% CO₂. HTM cells were used between passages 4-6 and HUVECs were used between passages 7-9. HUVEC cells were used as a model SC endothelial cell type for the purpose of understanding the regulation of adherens junctions and permeability characteristics.

Immunofluorescence staining and microscopy

HTM and HUVEC cells were grown on gelatin (2%)-coated glass coverslips until they attained confluency. For HTM cells, after appropriate treatments, cells were washed with phosphate buffered saline (PBS) twice and fixed in 4% paraformaldehyde/PBS for 15 min. Coverslips were then washed thrice in 1xPBS, cells permeabilized in 1% Triton X-100 in 1x PBS (PBST buffer) and blocked with serum buffer containing 5% FBS in PBST buffer for 60 min. The coverslips were incubated with the respective primary antibodies for 2 h at room temperature under humidity, and rinsed with permeabilization buffer followed by 3 washes with serum-containing buffer. The coverslips were then incubated with Alexa fluor 480 or 594-conjugated secondary antibodies in serum/PBS buffer for 2 h at room temperature and after three washes with 1x PBS, mounted onto glass slides with Aqua Mount (Lerner Laboratories, Pittsburgh, PA) [39]. HUVEC cells were washed twice in Hanks Buffered Salt Solution (HBSS) following treatment with the appropriate drug, fixed in 4% paraformaldehyde in HBSS for 20 min at room temperature. Cells were subsequently washed once with 0.1 M glycine in HBSS for 5 min and three washes with HBSS for 10 min. Blocking (1% Triton X-100 and 5% FBS in HBSS) was done for 1 h at room temperature, after which cells were incubated with the respective primary antibodies and Alexa fluor-conjugated secondary antibodies for 2 h at room temperature. Later, the coverslips were washed thrice with HBSS and mounted onto glass slides as described above. The slides were observed under a Nikon confocal system (CI Digital Eclipse), and z-stack images were collected and processed.

Adenovirus-mediated gene transduction

Replication defective recombinant adenoviral vectors encoding either LacZ alone or constitutively active Rac1 (Rac1G12V) and dominant negative Rac1 (Rac1T17N) were obtained from the Toren Finkel laboratory, National Heart Lung and Blood Institute, NIH [40,41]. The viral vectors were amplified and purified using the Adeno-x Maxi Purification kit (Clontech) as we described earlier [11]. HTM cells grown either on gelatin-coated glass coverslips or in plastic petri dishes to 80-85% confluency were infected with adenovirus at a multiplicity of infection (MOI) of approximately 70, as titrated using the Adeno-X Rapid titer kit (Clontech). After achieving more than 80% transfection efficiency (assessed based on LacZ immunostaining or Myc staining for Rac1G12V and Rac1T17N) at 36 h post-infection, cells were serum starved or maintained in low serum (1%) media for 24 h before being used in the respective experiments.

Myosin light chain phosphorylation

The effect of Rac inhibition by EHT1864 and Rac activation by PDGF on phosphorylation status of myosin light chain (MLC) in confluent cultures of HTM cells (serum starved for 24 h) was determined by urea-glycerol gel electrophoresis as we described earlier [39]. Briefly, confluent cell cultures were extracted with cold 10% trichloroacetic acid following treatment with PDGF or Rac inhibitors and cell precipitates collected after centrifugation at 13,000 rpm were washed and finally dissolved in 8M Urea buffer by sonication. 20 µg of protein was separated on urea-glycerol gel electrophoresis as we described above. The slides were observed under a Nikon confocal system (CI Digital Eclipse) and z-stack images were collected and processed.

Measurement of intracellular Reactive Oxygen Species (ROS) production

Intracellular ROS production was quantified with the cell-permeant ROS indicator 2',7'-dichlorodihydrofluorescein diacetate (H2DCFDA) [42]. Briefly, treated and control confluent HTM cells were trypsinized and incubated in 1 ml PBS containing 20 μM H2DCFDA for 30 min. After this loading period, the cells were washed with PBS, and the mean green fluorescence of 10,000 cells was immediately recorded and quantified by flow cytometry (BD FACSCalibur™) and the system software (FITC/FL-1 channel; CellQuest; BD Biosciences). Unstained control cells were included to evaluate baseline fluorescence. The laser intensity settings were adjusted to the lowest level at which autofluorescence was not detected.

**H₂O₂ and hyperoxia treatments**

HTM cell cultures (passage 4) were subjected to H₂O₂ treatment or hyperoxia conditions. For H₂O₂ treatment, confluent cultures of HTM cells were maintained in DMEM containing 1% FBS for 24 h, then treated with 250 μM of H₂O₂ for 3 h alone or in the presence of DPI (2 μM) or NAC (1 mM). For subjecting the HTM cell cultures to normobaric hyperoxia conditions, confluent cultures of HTM cells were grown for 7 days at 40% O₂ and 5% CO₂ in DMEM containing 1% FBS. On the other hand, the control cultures were grown under physiological oxygen conditions (5% O₂ and 5% CO₂) in a triple-gas incubator as described by Liton et al. [43]. These treatments were carried out in the presence and absence of DPI (2 μM) or NAC (1 mM).

**Transendothelial electrical resistance (TEER) measurement**

HTM cells (donor age 77, 64 and 55 years) were plated at confluence on polycarbonate Snapwell permeable supports (12 mm Snapwell insert with 0.4 m pore polycarbonate membrane #3407, Costar) and maintained in DMEM supplemented with 10% FBS until reaching a net TEER of at least 5 Ohm·cm² (by 5-7 days). Net TEER refers to the difference in the resistance of membrane containing confluent monolayer of cells compared to membrane alone. HTM cells were then maintained in DMEM containing 1% FBS or switched to DMEM/1% FBS containing the test compounds[Rac inhibitor NSC23766 (50 μM), DPI (2 μM), NAC (1 mM) or PDGF (10 ng/ml)] at their respective concentrations. In a separate experiment, PDGF was added after 6 h of pretreatment with either DPI or NAC. TEER measurements were recorded using an Endohm device (World Precision Instruments) as described by Perkumas and Stamer [44]. The net TEER was calculated by averaging the resistance collected from three independent Snapwell membranes for each treatment.

**IOP measurements in rabbits**

Experiments were performed on 6 healthy adult Dutch-Belted male rabbits weighing around 5 lb adhering to the NIH statement for the Use of Animals in Biomedical Research with approved protocol by the Duke IACUC. Intraocular pressure (IOP) was measured using a pneumotonometer after topical application of 0.05% proparacaine by the Duke IACUC. Intraocular pressure (IOP) was recorded using a pneumotonometer after topical application of 0.05% proparacaine by the Duke IACUC. IOP changes were immediately recorded and quantified by flow cytometry (BD FACSCalibur™) and the system software (FITC/FL-1 channel; CellQuest; BD Biosciences). Unstained control cells were included to evaluate baseline fluorescence. The laser intensity settings were adjusted to the lowest level at which autofluorescence was not detected.

Figure 1: Rac GTPase inhibitor induces cell shape changes in HTM cells. Confluent cultures of HTM cells were maintained overnight in 1% FBS were treated with Rac GTPase inhibitors- EHT1864 or NSC23766 (1 M to 50 μM; dissolved in PBS) for 6 h. After 4 h of exposure to EHT1864 (20 μM) or NSC23766 (50 μM), cells exhibited a contractile morphology, as assessed by phase contrast imaging, and relative to untreated control cells (Figure 1). There were no detectable changes in cell morphology at lower concentrations of drug (data not shown). The notable feature was that drug treated cells lost contact from adjacent cells but did not detach from the surface. These drug-
induced morphological changes were found to be reversible upon drug washout with PBS, with cells recovering a normal morphology by 24 h following drug removal. These drugs did not cause any notable cytotoxicity based on live cell labeling for the enzymatic hydrolysis of fluorescein diacetate and nuclear labeling using propidium iodide staining (data not shown); [39].

Treatment of confluent cultures of HTM cells maintained in 1% FBS with EHT1864 (20 µM) or NSC23766 (50 µM) for 4 h induced increased assembly of actin stress fibers at the cortical regions, confirmed by staining for F-actin (Rhodamine-Phalloidin) (Figure 2B and 2C) in both HTM (Figure 2B and 2C) and HUVEC (Figure 2F and 2K) cells, and increased focal adhesions formation (vinculin staining; green staining) especially at the leading edges (Figure 2B and 2C) in HTM cells, compared to corresponding controls (Figure 2A and 2I). β-catenin and VE-cadherin, components of adherens junction complexes, were immunostained in confluent cultures of both HTM and HUVEC cells. HTM cells exhibited a well-organized positive staining pattern/profile for β-catenin (2E), but not for VE-cadherin, while the HUVEC cells stained positively for both proteins (Figure 2M and 2Q), which were found to localize at the cell-cell contacts. Treatment with EHT1864 (20 µM) or NSC23766 (50 µM) for 4 h led to a decrease in β-catenin staining in HTM cells (Figure 2F and 2G), and decreased staining of both β-catenin (2N and 2O) and VE-cadherin (Figure 2R and 2S) in HUVEC cells, with disjointed cell-cell junctions compared to the controls (Figure 2E, 2M and 2Q). In contrast, inhibition of Rho kinase by Y27632 (5 µM) for 4 h, led to a loss of stress fibers and focal adhesions as well as adherens junctions in both HTM (Figure 2D and 2H) and HUVEC (Figure 2L, 2P and 2T) cells.

**Activation of Rac GTPase by PDGF induces adherens junctions in HTM and HUVEC cells**

PDGF has been demonstrated to activate Rac GTPase in various cell types including TM cells [30,47,48]. Serum starved (for 36 h) HTM and HUVEC cells treated with 10 ng/ml PDGF AA (dissolved in PBS) exhibited subtle morphological changes including membrane ruffle and lamellipodia-like structures based on F-actin (Rhodamine-phalloidin) staining by 1 h (Figure 3D and 3K, arrow heads) compared to controls (Figure 3A and 3G). Similarly, focal adhesions (based on vinculin staining in green) showed only a subtle reorganization (Figure 3E and 3L) in the PDGF treated cells compared to the controls (Figure 3B and 3H). Under similar treatment conditions, we examined the effects of PDGF on distribution of β-Catenin and VE-Cadherin by immunofluorescence labeling. In HTM cells, β-Catenin staining was found to be more prominent at the cell-cell junctions under PDGF stimulation (Figure 3F) compared to the control (Figure 3C). In unstimulated HUVEC cells, β-Catenin atenin and VE-Cadherin staining was seen along the cell-cell contact area (Figure 3I and 3L, respectively) but upon stimulation with PDGF (10 ng/ml for 2 h), the staining intensity of these molecules was found to be much stronger compared to the controls (Figure 3M and 3N). Under these conditions, the cell shape changes were found to be not obviously different between the treated and control cells based on phase contrast microscope imaging (not shown).

**Effects of constitutively active and dominant negative forms of Rac1 GTPase on adherens junctions in HTM and HUVEC cells**

In order to assess the role of Rac GTPase signaling on the properties of adherens junctions in HTM and HUVEC cells, these cells were infected (80% confluent) with the adenovirus (at 70 MOI) expressing either the constitutively active (Rac1G12V) or dominant negative (Rac1T17N) forms of Rac GTPase, or a LacZ control. Infection efficiency was evaluated based on β-galactosidase expression by immunoblotting (data not shown) or by immunofluorescence labeling. By around 36 h post infection, nearly 80% of the cells expressed detectable levels of β-galactosidase or LacZ protein. The cells infected with Rac1G12V were serum starved for 24 h (after 36 h of virus infection), while the cellsinfected with Rac1T17N or LacZ vectors were maintained in 1% FBS media. The LacZ expressing HTM and HUVEC cells revealed no changes in either actin cytoskeleton organization or cell-cell junctions compared to their respective non-infected controls (data not shown). The Rac1G12V expressing HTM (Figure 4E) and HUVEC (Figure 4F) cells exhibited only subtle changes in focal adhesions organization but stronger β-catenin (in both HTM and HUVEC cells; Figure 4H and 4Q) and VE-Cadherin (in HUVEC cells; Figure 4T) staining at

![Figure 2: Rac GTPase inhibitor-induced effects on actin cytoskeleton, focal adhesions, and adherens junctions in HTM and HUVEC cells.](image-url)

**Figure 2:** Rac GTPase inhibitor-induced effects on actin cytoskeleton, focal adhesions, and adherens junctions in HTM and HUVEC cells. Confluent cultures of HTM and HUVEC cells maintained overnight in 1% FBS were treated with either Rac inhibitors EHT1864 at 20 µM (B, F, J, N, R) or NSC23766 at 50 µM (C, G, K, O, S), or with Rho kinase inhibitor (Y-27632) at 5 µM (D, H, L, P, T) for 4 h. EHT1864 and NSC23766 both induced reorganization of actin stress fibers (Rhodamine-phalloidin staining; red) to the cell cortical region and clustering of focal adhesions (vinculin staining; green) to the leading edges in both HTM and HUVEC cells (B, C, J, K) compared to controls (A, I). In these cell types, Rho kinase inhibition led to cellular relaxation manifested by decreased actin stress fibers and focal adhesions (D, L). β-Catenin immunostaining was decreased in both HTM and HUVEC cells after treatment with Rac inhibitors (F, G, N, O) or Rho kinase inhibitor (H, P) and relative to controls (E, M). HUVEC cells showed a loss of VE-cadherin staining and increased intercellular gaps upon inhibition of Rac GTPase (R, S) or Rho kinase (T) and compared to the control (Q). Scale bar: 10 µm.
the cell-cell junctions compared to the LacZ controls (Figure 4D, 4G, 4M, 4P and 4S). In contrast, the Rac1T17N expressing HTM (Figure 4C and 4F) and HUVEC (Figure 4L and 4O) cells displayed strong cortical actin staining with much reduced and discontinuous staining of β-catenin (in both HTM and HUVEC cells; Figure 4I and 4R) and VE-cadherin (in HUVEC cells; Figure 4U), indicating loss of cell-cell junctions in response to overexpression of the dominant negative form of Rac1 in both HTM and HUVEC cells. Under above described conditions, the cell shape of either HTM or HUVEC cells exhibited no marked differences from the respective control cells based on phase contrast microscope examination (data not shown).

Influence of Rac GTPase inhibition on MLC phosphorylation in HTM cells

Myosin light chain (MLC), which is the regulatory subunit of myosin II, is phosphorylated by myosin light chain kinase (MLCK) and Rho kinase, and phosphorylation of MLC controls actin-myosin II cross-bridging, leading to cellular contraction [49,50]. Here we tested the effects of Rac GTPase activity on MLC phosphorylation in HTM cells (Figure 5). Treatment of confluent cultures of HTM cells maintained in 1% FBS (overnight) with EHT1864 (20 µM for 2 h) led to an increase, albeit insignificant, in the levels of MLC phosphorylation compared to the respective controls. On the other hand, stimulation of serum starved HTM cells with human recombinant PDGF (10 ng/ml) caused a slight decrease in MLC phosphorylation, as has been reported earlier [15]. PDGF stimulation which is expected to activate Rac GTPase activity in human TM cells [30] pretreated with Rac inhibitor (EHT1864 for 4 h) did not lower the levels of MLC phosphorylation (Figure 5). β-Tubulin was immunoblotted for loading normalization.

Formation of Rac GTPase-mediated adherens junctions is dependent on ROS production in HTM cells

Rac GTPase signaling has been shown to regulate the generation of ROS by activating the NADPH oxidase system [51,52]. To explore whether ROS are generated and in turn influence cell-cell interactions in HTM cells, confluent cultures (maintained under serum free conditions) were stimulated either with PDGF (10 ng/ml for 4 h)
or by overexpression of Rac1G12V (for nearly 48 h), followed by determination of ROS levels by flow cytometry using the H$_2$DCFDA substrate. There was a significant increase (nearly two fold; p < 0.05) in the amount of ROS production under both conditions known to promote Rac activation (i.e., PDGF stimulation and overexpression of Rac1G12V, Figure 6A and 6B, respectively). Presence of Rac inhibitor EHT1864 (20 µM for 4 h) or overexpression of dominant negative Rac (RacT17N) for 48 h (in 1% serum) per se caused a significant (~10 and 14%, respectively) decrease in ROS levels, compared to the basal ROS levels in LacZ transfected or untreated control cells (Figure 6A and 6B). Quenching of ROS by NAC (1 mM N-acetyl cysteine for 2 h; dissolved in PBS) or inhibition of the NADPH oxidase system by DPI (2 µM diphenyleneiodonium for 2 h; dissolved in DMSO) led to a significant (~11 and 15%, respectively) decrease in ROS levels (Figure 6A) in HTM cells. The levels of ROS were rescued only partially but not significantly by PDGF treatment (10 ng/ml for 2 h) in cells initially exposed to either DPI or NAC (2 µM or 1 mM respectively for 2 h) as compared to the controls. Both DPI and NAC (2 µM or 1 mM, respectively for 2 h) attenuated the effect of Rac1G12V on increase in ROS production in HTM cells (Figure 6B).

To determine the significance of Rac GTPase-induced ROS production in maintaining the adherens junctions in HTM cells, we scavenged ROS using NAC (1 mM for 2 h) or suppressed the production of ROS with DPI (2 µM for 2 h) after an overnight serum deprivation.
deprivation (1% FBS condition) step. The status of adherens junctions was assessed by immunofluorescence labeling of β-catenin and VE-cadherin in NAC/DPI treated HTM and HUVEC cells (Figure 7B, 7C, 7H, 7I, 7N and 7O) relative to control cells (Figure 7A, 7G and 7M), and in the PDGF treated cells (10 ng/ml for 2 h) maintained under serum free conditions (Figure 7D, 7J and 7P). Under these conditions, the adherens junctions staining was not uniform along the cell-cell contacts and resulted in intercellular gaps in NAC and DPI treated cells. The loss of cell-cell junctions as assayed by β-catenin (in both HTM and HUVEC cells) and VE-cadherin (in HUVEC cells) immunostaining was not rescued by PDGF treatment (10 ng/ml for 2 h) in HTM (Figure 7E and 7F) or HUVEC (Figure 7K, 7Q, 7L and 7R) cells pretreated with either NAC or with DPI, demonstrating the importance of ROS in Rac1-induced adherens junction formation in both HTM and HUVEC cells.

Effects of ROS production induced by H2O2 or hyperoxia on adherens junctions and TEER in HTM cells

To further explore the involvement of ROS signaling in maintenance of cell-cell junctions, we assessed the effects of H2O2 (250 µM) or 40% oxygen by immunofluorescence labeling of β-catenin in HTM cells. When treated with H2O2 (250 µM) for 3 h or under hyperoxia (40% oxygen) for 7 days, the HTM cells displayed strikingly intense β-catenin immunostaining labeling. But this response of H2O2 and hyperoxia was attenuated in the presence DPI or NAC (Figure 8A and 8B).

Table 1: Effects of PDGF, H2O2 and Rac inhibitor on Transendothelial Electrical Resistance (TEER) of HTM cell monolayers.

Then to investigate the functional effects of Rac signaling and ROS generation on the TEER, we carried out the measurements of TEER on fully confluent monolayer of HTM cells (Figure 8A and 8B). As determined by the TEER measurements, the basal net electrical resistance was on an average around 7.9±0.9 ohm.cm². Activation of Rac GTPase by PDGF that increases ROS or treatment with H2O2 (250 µM) significantly increased the net resistance to 11.0±1.4 and 10.6±1.5 ohm.cm², respectively after 6 h of treatment. On the other hand, treatment with Rac inhibitor, NSC23766 (50 µM), showed a significant decrease in the TEER to 5.2±0.8 ohm.cm² at 8 h and then the TEER came back to the baseline by 24 h. Treatment with NAC, which quenches ROS, led to a significant decrease in resistances 5.7±1.4 ohm.cm² by 6 h and this decrease in resistance was not rescued with the presence of either PDGF or H2O2 confirming the significance of ROS in regulation of TM cell TEER (Table 1). Individual net TEER values are presented.
To confirm drug penetration through the cornea into the anterior chamber of rabbit eyes described above, drug (NSC23766) concentrations were monitored by LC-MS analysis of AH samples drawn after 1 h of topical application of 50 mM NSC23766. This analysis revealed that an average of ≈ 50 nM of the drug penetrated into the aqueous humor of rabbit eyes (based on an average of two independent samples). This observation confirms that the drug is capable of penetrating into the AH. The levels of EHT1864 were not determined.

**Discussion**

Our primary objective of this study was to test the hypothesis that the integrity of adherens junctions in cells of the AH drainage pathway may influence IOP. To test this, here we investigated the regulation of adherens junctions formation in HTM cells in comparison with HUVECs cells by Rac GTPase and assessed the effects of modulators of Rac GTPase activity on IOP in rabbits. This study reveals that a. Rac GTPase and its physiological activator PDGF induce adherens junctions formation in cultured HTM and HUVEC cells in association with changes in actin cytoskeletal reorganization and cell-ECM interactions, b. Rac GTPase activation in HTM cells induces ROS production via NADPH oxidase, c. Suppression of Rac GTPase activity and ROS production in HTM and HUVEC cells impairs adherens junctions formation in both these cell types, d. Hyperoxia, H2O2 and PDGF increase ROS, adherens junctions and transendothelial electrical resistance (TEER) in HTM cells, and finally e. topical application of Rac GTPase inhibitors appears to have a marginal effect on IOP in live rabbits.

Increased resistance to AH drainage through the conventional pathway is the main cause for elevated IOP in primary open glaucoma [3,17,18]. Although the precise location of resistance to aqueous drainage within the conventional pathway is not well defined, increased permeability barrier between the inner wall of the SC cells due to increased cell-cell interactions is thought to be one of the possible cellular bases for increased resistance to outflow [4,5,7,14]. Although, this possibility has been supported partly by perfusion studies using actomyosin interfering agents, calcium chelators, kinase inhibitors, dexamethasone and growth factors [4,7,14,15,29,53], the direct role of adherens junctions in IOP homeostasis has not been investigated. To understand the regulation of adherens junctions formation in cells of the AH outflow pathway, which are recognized as the predominant type of cell-cell junctions of endothelial cells [16,54,55], we investigated the role of PDGF which is an activator of Rac GTPase signaling [30,48]. Stimulation of confluent cultures of the HTM and HUVEC cells with PDGF induced formation of β-catenin-based cell-cell junctions in a Rac GTPase-dependent manner. In contrast, Rac GTPase inhibitors and a dominant negative mutant of Rac GTPase caused a decrease in the basal level of adherens junctions in both HTM and HUVEC cells. PDGF has previously been reported to activate Rac GTPase activity in TM cells [30]. Moreover, in both HTM and HUVEC cells, expression of constitutively active Rac GTPase induced a robust increase in adherens junctions formation, confirming the direct influence of Rac GTPase signaling on adherens junctions formation in the outflow pathway cells. Similar to the HUVECs tested in this study, SC cells which are endothelial in nature, have been reported to develop VE-cadherin based cell-cell junctions [31]. Therefore, the HUVEC cells used in this study are

in Table 1 as Mean±SD (n=3) and p values are indicated where they are significant.

**Rac GTPase inhibitors and IOP**

To determine the involvement of Rac GTPase signaling in modulation of intraocular pressure (IOP), we tested the effects of Rac GTPase inhibitors on rabbit IOP by topical application of EHT1864 (25 mM) or NSC23766 (50 mM). Maximum concentration of drug that could be dissolved in PBS was used in these experiments. Administration of a single dose (two 30 μl drops) of drug did not cause significant change in IOP relative to controls (vehicle treated, contralateral eye) during the 24 h interval following drug treatment (Figure 9). The baseline IOP of control eyes (PBS applied) was 24±2 mm Hg for the EHT1864 control group and 26.6±2 mm Hg (NSC23766 control group). IOP changes were monitored for 24 h and there was only a marginal (statistically insignificant, values represent Mean ± SEM, n=6) difference (decrease of 1-2 mm Hg) between the drug treated and control eyes.

**Figure 9:** The effects of Rac GTPase inhibitors on IOP in Rabbits. To determine the role of Rac GTPase activity in regulation of IOP, the Rac GTPase inhibitors; NSC23766 (50 mM) or EHT1864 (25 mM) were dissolved in PBS, adjusted to pH 7, then applied topically (two 30 μl drops with a one minute delay) to one eye while the other eye was used for the vehicle treatment. The drug was administered only once per animal. Baseline IOP (recorded using a pneumotonometer) in PBS treated control eyes was 24±2 mm Hg (EHT1864 control group) and 26.6±2 mm Hg (NSC23766 control group). IOP changes were monitored for 24 h and there was only a marginal (statistically insignificant, values represent Mean ± SEM, n=6) difference (decrease of 1-2 mm Hg) between the drug treated and control eyes.
not identical to SC cells but are expected to serve as a model cell type for SC cells in the context of adherens junctions and permeability characteristics.

To identify the downstream effectors mediating the effects of PDGF and Rac GTPase on adherens junctions in cells of the AH outflow pathway, we measured the levels of ROS which are the product of the Rac activated NADPH oxidase system [35,56-58]. Unlike other members of the Rho and Ras family of GTPases, Rac GTPase is one of the components of NADPH oxidase, a multi-component enzyme producing ROS in phagocytic and non-phagocytic cells [24,35,42,51]. ROS have been shown to play a regulatory role through a redox mechanism [52,59] involving for example the tyrosine phosphorylation of various signaling molecules, via targeting the activity of tyrosine phosphatases through cysteine oxidation [58,60].

Both PDGF and constitutively active Rac GTPase were found to stimulate ROS production significantly in HTM cells. Importantly, inhibition of NADPH oxidase by the flavoprotein inhibitor DPI, or quenching of ROS by the antioxidant NAC in HTM cells, reduced and disrupted the PDGF and constitutively active Rac- induced formation of adherens junctions, confirming that ROS play a critical role in adherens junctions formation in the endothelial cells of the outflow pathway. Additionally, both H$_2$O$_2$ and hyperoxia (40% O$_2$) in HTM cells were found to induce formation of adherens junctions in ROS dependent manner.

In a previous study by Syriani et al. [30] have reported that perfusion of PDGF increases AH outflow facility in bovine eyes, and topical application of the same compound in rabbits decreases perfusion of PDGF increases AH outflow facility in bovine eyes, which has been shown to activate Rac GTPase activity in SC cells has also been reported to lower humor outflow facility by the Rho kinase- specific inhibitor Y-27632. Invest Ophthalmol Vis Sci 42: 1029-1037.

ROS have also been shown to play a critical role in adherens junctions formation in the endothelial cells of the outflow pathway. Additionally, both H$_2$O$_2$ and hyperoxia (40% O$_2$) in HTM cells were found to induce formation of adherens junctions in ROS dependent manner.

In an alternative scenario, it is also conceivable that the PDGF-induced decrease in IOP is due to increased Rac GTPase activation leading to ROS production with subsequent destabilization of adherens junctions via ROS-induced phosphorylation of adherens junctional complex proteins, similar to what occurs in microvascular endothelial cells treated with VEGF [28]. However, in HTM cells, increased ROS production was found to be correlated well with increased TEER. But as a precautionary note we cannot rule out with certainty that the lack of significant changes in IOP in response to inhibitors of Rac GTPase noted in this study was not due to inadequate in vivo levels of drug within the eye.

To unravel a definite role for Rac GTPase in AH outflow facility, future studies are necessary to evaluate the effects of expressing constitutively active and dominant negative mutants of Rac GTPase in the anterior segments of the organ cultured eye on AH outflow facility as well as cell-cell junctions in outflow pathway tissues of different species.
