Surgery without Sufficient Indications: an Update from Russia

Keywords: Peptic ulcers; Gastrectomy; Portosystemic Shunting; Asthma; Lung resection; Bronchoscopy; Medical ethics

Abstract
This review is an update and continuation of preceding papers on invasive procedures applied in Russia with questionable clinical indications. Certain methods have been applied according to instructions by healthcare authorities and publication of leading specialists, facilitated by lacking professional autonomy. Examples are discussed here and in preceding papers: the overuse of Halsted and Patey mastectomy, preventive electrocoagulation of cervical ectropions without cytological examination, gastrectomy for peptic ulcers, thoracic and abdominal surgery for bronchial asthma and diabetes mellitus, overuse of surgery in tuberculosis and other pulmonary conditions, overuse of bronchoscopy e.g. in conscripts with supposed pneumonia. Among mechanisms contributing to the persistence of suboptimal methods has been the autocratic or military managerial style discouraging criticism and polemics. Other attributes of this style are the paternalistic approach to patients and insufficient adherence to the principle of informed consent. Some invasive procedures with questionable indications were advocated by first generation military surgeons. Personnel training could have been one of the motives. Note that military and medical ethics are not the same. The comparatively short life expectancy in Russia is a strategic advantage as it necessitates less healthcare investments and pensions. Actually, Russia needs foreign help in the matter of healthcare. In view of the current international tensions, the cooperation has been partly interrupted. Obstacles to the import of medical products have adverse consequences. Under these circumstances, the purpose of this article was to remind that, performing a surgical or another invasive procedure, the risk-to-benefit ratio must be kept as low as possible. Insufficient coordination of medical studies and partial isolation from the international scientific community can result in parallelism in research, unnecessary experimentation, and application of invasive methods without sufficient indications.

Introduction
This review is an update and continuation of preceding papers on invasive procedures applied in Russia with questionable clinical indications [1,2]. According to the author’s estimates after his practice abroad, an average size of malignant tumors in surgical specimens was larger in Moscow clinical centers than in hospitals of Western Europe and Southern Africa. Obviously, this reflects the efficiency of cancer diagnostics. Another difference: almost all mastectomy specimens independently of tumor size were presented as the main or singular treatment modality of breast cancer. In the 1980s and decreasingly during the 1990s, Halsted procedure remained unnoticed in the former Soviet Union (fSU) for decades. The Halsted procedure is known to be associated with complications; in some textbooks and monographs edited in the 21st century [3-5]. Mikhail Kuzin recommended the modified radical mastectomy of Patey with the removal of pectoralis minor muscle [7]. This latter procedure is also associated with adverse effects; it has been broadly used in Russian Federation in the last decades. During the author’s practice (1995-1998) at the pathology department of the Ostroumov hospital in Moscow, incorporating the Center for Breast Diseases, almost all mastectomy specimens independently of tumor size included the pectoralis minor muscle; but Halsted procedure with the removal of both pectoral muscles was applied as well. Newly developed mastectomy modalities with the muscle removal were patented [8,9]. Today, textbooks and guidelines are being adjusted to international prototypes. However, questionable recommendations have remained without due commentaries, so that a reversion to suboptimal practices is not excluded.

Diabetes mellitus
The "pancreatic blood shunting into the systemic blood flow" was introduced by Eduard Galperin and applied as a surgical treatment of moderate to severe insulin-dependent diabetes mellitus [10-20]. At the same time Galperin wrote: "Patients with diabetes tolerate surgery generally very poorly" [20]. The same operation was applied also in type 2 diabetes [11,12]. The physiological rationale appears unconvincing: "Creating a more optimal interaction of subcutaneously administered insulin and pancreas-secreted glucagon" [13]. Among 415 patients, early post-operative complications were observed in 28 patients including 2 cases of sepsis, ileus (1), pyelonephritis (5), pneumonia (5 cases); 2 patients died during the first week post-surgery. Ketonuria was observed in 18 cases agreeing with the known fact that the surgical stress can provoke ketosis in diabetics [10]. Comparable percentages of complications were reported in [13]. The patients were subdivided into groups with a good, satisfactory and no effect [14]. There was no group with complications or worsening, so that the evaluation was probably biased. Apart from several publications from Russia and Ukraine [10-20], no reports on this kind of diabetes treatment were found. Thrombosis of the splenorenal anastomosis was found by angiography in 27% of the patients during eight months post-surgery [15]. Severe acidosis was designated as typical occurrence [15,16]. The anti-diabetic effect of the shunting was reported to be
According to the ex-Soviet health minister Boris Petrovsky, Yudin’s hyper-radicalism in the military surgery, followed by colleagues, “led to hemorrhages, large defects of soft tissues and bones” [32]. Yudin’s articles recommending gastric resections for ulcers were reprinted with approving comments [29]; his works continue to be cited [33-35]. Gastric resections have been advocated for perforated ulcers by many Russian surgeons [22,25,36-40]. The broad acceptance of this procedure has been attributed to the limited availability of modern drug therapy [22,25]. In some papers advocating gastric resection for ulcers, it was suggested that the “modern medical treatment does not completely solve the problem” [40] and “…does not lead to a complete recovery”, so that the surgery must be implemented early enough to prevent complications [37]. This approach is generally at variance with the international practice [41].

Respiratory diseases

Another procedure with no analogy in the contemporary international practice is the thoracotomy with lung denervation in bronchial asthma designated as “the most recognized method” in the guidelines issued by the Ministry of Health [42-46]. The method was propagated by the former military surgeons Stepan Babichev and Evgeniy Meshalkin [42,46], who applied “autotransplantation” of lungs in asthmatics [47]. The denervation was applied because it supposedly “interrupts pathological impulses from the nervous system” [42]. Such argumentation was usual in the Soviet-time literature, when the so-called ideas of nervism, based on the concept of trophic function of the nervous system by Ivan Pavlov, were propagated. In particular, exaggerated histological descriptions of “dystrophy” or degeneration of neural structures such as ganglia of the autonomic nervous system were presented in support of the denervation [42]. The procedure was recommended by the Health Ministry while thoracotomy with the pulmonary root skeletonization was called “the most recognized surgical procedure to treat severe asthma” [43]. The skeletonization method was patented and recommended for both steroid-dependent and “infectious-allergic” asthma [43,48]. After the surgery, repeated bronchoscopies were recommended because of the bronchial drainage impairment [46]. Lung denervation, segment- and lobectomies were advocated also when the medical treatment of asthma “was temporarily effective.” It was suggested that medical therapy prior to the surgery should be of limited duration [43]. A group of experts performed surgical denervations in 457 asthmatics. Among them, the following complications were noticed: inflammation in general (27 patients), pneumonia, empyema, pneumothorax (11), dysphagia, vocal fold palsy, Horner syndrome (12), paraplegia, hemiparesis (2); post-operative complications in general (58 cases); 6 patients died within 32 days post-surgery [45]. By 2002, the method was still in use [44]. The denervation surgery was sometimes combined with a resection of pulmonary segments or lobes deemed pathologically altered [43].

Lung resections were applied as a standalone method of asthma treatment, even in the cases when medical therapy was effective. Indications for surgery included local pulmonary and bronchial lesions: chronic pneumonia, bronchiectasis, pneumocirrhosis and bronchitis deformans (both latter terms have been used in SU) [49]. It was reported by some experts that “no more than 10%” of their asthma patients had been treated by lung resections [50]. Operations were carried out when the lesions were extensive and bilateral, thus being

Peptic ulcers

Certain surgical treatments of gastroduodenal ulcers in FSU have been different from the international practice [22]. According to the author’s observations, gastric resections were rarely performed abroad for peptic ulcers; the volume was smaller, usually corresponding to antrectomy. For perforated ulcers, a local excision was usually performed, while a specimen resembling a wide wedding ring with staples was sent for the histological examination. Another approach is the laparoscopic repair [23]. In Russia, the primary gastrectomy (2/3-3/4 of the stomach), antrectomy with vagotomy, or a simple suture (depending on the patient’s condition) has usually been performed [24-26]. In 2014, a simple closure (sutting) was carried out in 80% of ulcer perforations in Russia [27]. Admittedly, recent guidelines include ulcer excision along with a suturing and gastric resection among recommended procedures for perforated ulcer. The limited availability of modern medical therapy was called a “social indication” for gastrectomy in patients with peptic ulcers [25]. During the 1960-1970s, when gastrectomy was practically the only available surgical treatment of peptic ulcers, complications were noticed [22,28]. The hyper-radicalism in the gastric surgery originates from the well-known surgeon Sergei Yudin (the spelling Iudin is currently used in the international bibliography [29]). He was an “enthusiastic advocate of gastric resection in cases of acute perforation” [30]. According to his doctrine, the pylorus and lesser curvature must be completely removed at an ulcer surgery [29]. During the Second World War, Yudin was one of the chief surgeons of the army. He was known for the advocacy of hyper-radicalism: “Really wide and complete excision of all devitalized tissues... excision rather than drainage and removal of bone fragments in joint wounds (including knee and even hip)” [30]; “Decisively sacrifice healthy muscles to access the fracture” [31]. According to the ex-Soviet health minister Boris Petrovsky, Yudin’s
not completely removable, also during remissions, regarded to be indicated for a radical healing of asthma. This concept was advocated by the well-known surgeon Fedor Uglov [49,51], who declared a "removal of the infectious focus" to be the main purpose of asthma treatment. The surgical treatment of asthma was based on the Uglov's belief that "in 98% of cases, the basis of bronchial asthma is chronic pneumonia" [49]. Chronic pneumonia was declared to be "the basis of bronchial asthma". The main purpose of the asthma surgery was "elimination of the infectious focus". Localized chronic pneumonia with bronchial lesions was by itself regarded to be an indication for lung resection. Asthmatics were transferred from therapeutic departments for the surgical and bronchosurgical treatment. "After a course of therapeutic bronchoscopies" [49], Uglov and co-workers performed segment- and lobectomies, removing pulmonary tissues regarded abnormal by them [49,51]. The same treatment was applied to children with persistent cough and recurrent pneumonias. This doctrine was supported by certain pathologists, who described in surgical specimens inflammatory infiltrations, fibrosis, dystrophy and malformations without specifying their extent and hence functional significance [52-56]. The surgery was claimed to be favorable also in children in view of supposedly "almost inevitable inflammatory complications" of congenital malformations [54], which might be true for some cases. However, lengthy histological descriptions of supposed malformations partly at variance with the standard editions of pulmonary pathology might have contributed to surgeries beyond clinical indications.

Pulmonary tuberculosis

After the introduction of efficient drug therapy in the 1950-1960s, the surgical treatment of tuberculosis (Tb) has been partly abandoned in many parts of the world. The role of surgery remains controversial. The priority of surgery in Russia in this field was pointed out [57-59]. The Tb surgery has been applied not only in large centers but also in peripheral hospitals [59,60]. This development was associated with the names of Lev Bogush (1905-1994) and Mikhail Perelman (1924-2013) [59-63]. According to Bogush, "surgery must occupy the leading position in the integral Tb treatment instead of being a last resort for cases of ineffective drug therapy" [60]. He claimed that even severe respiratory insufficiency is not a contraindication for lung resection [62]. Perelman became director of the Institute for Phthisiopulmonology at the Sechenov Moscow Medical Academy in 1998. It was time when the World Health Organization (WHO) promoted the directly observed treatment, short course (DOTS) program in Russia. Perelman called this WHO program absurd, insisting that surgery must be applied in the Tb treatment more often [63].

From 1973 through 1987, 285,000 patients with pulmonary Tb were operated on in fSU, in 1987 - 26,000, whereas 85% of the operations were lung resections [64]. In the period 1986-1988, 17,000-18,000 operations for pulmonary Tb were performed yearly in the Russian Soviet Republic (part of fSU) only in specialized phthisiological hospitals [57]. The incidence of Tb in 1986 and 1988 was, respectively, 43.8 and 40.8 per 100,000 [65]. Taking into account the population of Russia, ≥29 surgeries per 100 newly diagnosed Tb cases (≥29%) were performed in those years. In 2003, 10,479 surgeries (9% of new cases) were carried out, considered "extremely insufficient" [66]. In the international literature, corresponding figures are generally ≤5% [67-69]. At the same time, the incidence of Tb in Russia increased from 34.0 in 1991 up to 90.4 per 100,000 in 2000 [65]. By analogy with other diseases [70], an artefact can be behind the "huge variation" of Russian statistics [71]. The incidence of Tb could be understated during the Soviet time.

In 2006, 12,286 surgeries were performed in Russia for pulmonary Tb including 9300 (75.7%) lobectomies and other resections as well as 399 (3.2%) pneumonectomies [58]. According to another report, the forms of Tb most frequently treated by resections and pneumonectomies were cavitary Tb (52.2%) and tuberculoma (43.9%) [72]. Above-named operations were performed and recommended also for patients with inactive post-tuberculous fibrosis including cases with sparse symptoms [73]. At the same time, surgeries were performed in disseminated Tb [74]. In some provinces (Kemerovo, Chelyabinsk, Moldovia), 25-40% of patients with destructive Tb were operated on [75]. At the time of initial Tb diagnosis, surgery was considered to be indicated in 15-20% of patients [57]. According to another paper by the same authors, indications for surgery were found in 20-30% of patients at the time of initial diagnosis and/or among cases of active Tb [76]. In Yekaterinburg and surrounding province (2006-2008), indications for surgery were found in 1784 from 4402 (40.5%) patients with pulmonary Tb, whereas 1079 (24.5%) were operated on. Among reasons of the relatively "low" surgery rate were the patients' non-compliance and unavailability [77]. According to the last (2020) edition of the Phthisiology textbook, 6,1-6,7% of Tb patients are currently operated on in Russia; however, "in some regions that have actively cooperated with the M.I. Perelman Institute for Phthisiopulmonology… the percentage has been several times higher" [78]. As mentioned above, in the international literature corresponding figures are generally ≤5% [67-69]. Tb surgery may become more topical due to the multidrug resistance. According to a current estimate from Russia, the need for surgery has increased up to 15% over the last twenty years [79]. Despite the lack of clinical trial data on efficacy of adjunctive surgical therapy, some countries of fSU have continued to perform many surgical interventions, mainly resections [80,81].

Tuberculoma (>2 cm, also in children) has been generally regarded in Russia as an indication for surgery [78,82]. The same experts designated fibrocavitary Tb as an absolute indication [78]. Tuberculomas >1 cm were routinely operated on [83-85], which is generally at variance with the international practice. There is an opinion that potential instability of tuberculoma does not justify thoracic surgery and that asymptomatic patients with an unchanging solid focus do not require treatment. Tuberculoma as an indication for pulmonary resection was seen differently from other forms of Tb where surgical risks could be justified by a poorer prognosis. Nevertheless, tuberculoma was the most frequent indication for lung surgery in Tb patients at the Sechenov Medical Academy (44.2%) [58], while at some other institutions this percentage has been 50-80% [86]. In particular, tuberculoma was the most frequent indication for surgery in adolescent Tb patients [82]. Children were routinely operated on for tuberculomas, non-specific inflammatory, fibrotic lesions and bronchiectasis [87,88]. The surgical treatment of tuberculoma was officially recommended also for cases with extensive lesions in remaining pulmonary tissue [89]. Bilateral resections were
performed for various forms of Tb including solitary tuberculomas on both sides [90-92]. A study from the Sechenov Academy reported 771 lung surgeries, including 180 pneumonectomies, 181 lobectomies and bilobectomies, 180 smaller resections, performed in 700 Tb patients with drug resistance, up to 4 operations per patient. Postoperative complications were observed in 100 cases (12.9%), fatal outcomes - in 12 (1.5%) [93]. Another example from the same institution: among 60 operated Tb patients (16 pneumonectomies, 24 lobectomies and smaller resections) the complication rate was 37%, mortality - 5%; 18.3% of the patients were discharged from the hospital with persisting complications [94].

Resections were performed by some experts for tuberculoma, infiltrative and cavitary Tb without preceding medical treatment or within one month after the diagnosis i.e. when medical therapy could have been efficient [84,95]. One of the arguments in favor of early surgery was the non-compliance increasing with time [84], apparently, as the patients collected more knowledge about their disease and advice from other patients. In diabetes mellitus, a surgery was recommended for tuberculoma after 2-5 months of medical therapy. The authors operated also asymptomatic patients and recorded an overall 15.73% rate of complications [96]. Apparently, complication rates have been underestimated due to limited follow-ups. Lung surgeries for Tb were performed and recommended also for aged patients with comorbidities [97-100]. Sokolov found indications for surgery in 210 from 289 (72.6%) Tb patients 50-73 years old and operated 180 (62.2%) of them, 144 operations being lung resections. Among the latter 144 patients, 93 (66.4%) had cavity disease and 43 (30.8%) - tuberculoma. A post-surgery reactivation of Tb was recorded in 8.6%, fistula - 27.2%, atelectasis - 20%, pneumonia - 5.7%, pleural empyema - 3.6%, other complications - 12.9% of cases; 8 (5.7%) patients died after operations [97]. In the monograph based on 233 lung resections in Tb patients older than 50 years (mortality 5.4%), Sokolov reasonably concluded that “it is important that a surgery would not accelerate an unfavorable outcome” [98]. According to another report, tuberculoma was the most common indication, and lobectomy - the most frequent modality in elderly Tb patients, whereas potential contagiosity was among arguments in favor of the surgical treatment [100]. Statements of this kind can be found also in recent papers e.g.: “Surgery in patients with tuberculomas is recommended to reduce their infectiousness” [79]. Note that tuberculoma is infrequently contagious. In the author’s opinion, (potential) contagiosity does not justify a thoracic surgery. In any case, patients must be comprehensively informed about possible risks and benefits to be able to make an independent decision according to the principle of informed consent.

Bilateral resections were performed in various forms of Tb including tuberculomas on both sides or tuberculoma plus cancer [90-92,101,102]. Indications for a second lung surgery were found in 20-37% of previously operated cases [103]. Out of 1311 Tb patients operated at the Sechenov Medical Academy during 1989-2001, 241 developed relapses. After excluding 8 patients with contraindications, a second surgery was performed in 84 out of 241 (35%) previously operated patients [103]. Postoperative relapses of Tb were regarded as indications for repeated surgeries up to a “concluding pneumonectomy” and resections of the single lung [91,101]. For example, repeated resections on both sides with a concluding pneumonectomy along with 52 bronchoscopies were reported in one Tb patient [104]. As mentioned above, the lung resection or pneumonectomy was deemed applicable even in cases with severe respiratory insufficiency [60,62,101,105]. Bilateral resections or pneumonectomy plus contralateral “economic” (sparing) resection were deemed indicated for patients with a Tb lesion on one side and non-specific inflammatory or fibrotic lesion on the other side [106].

The role of surgery in Tb remains controversial. Clinical recommendations are beyond the scope of this review. The message is that patients should not undergo surgeries, bronchoscopies and other invasive procedures to comply with instructions and doctrines without sufficient evidence-based indications, possibly fed by motives such as personnel training, of military surgeons, endoscopists etc. The approach should be individual based on a consensus expressed in the international literature. The principle of informed consent must be observed - patients received all information on potential benefits and risks to be able to make an independent decision with proper understanding. The informed consent began only recently to be mentioned in papers from ISU reporting research using invasive methods, for example in a bronchoscopic study of childhood asthma, where the consent of parents was regarded to be sufficient [107]. Of note, the principle of informed consent or assent is applicable also to adolescents and children.

The outpatient treatment of Tb, usual in other countries, was supposed to be hardly applicable in Russia [108]. According to the governmental Ordinance No. 378 of 16 June 2006, patients with contagious Tb are not allowed to live in one apartment with other people. As per the Federal Law No. 77 “Prevention of the spread of Tb in Russia” of 18 June 2001 (amended 2013), “patients with contagious forms of Tb, repeatedly violating the sanitary and anti-epidemic regime, as well as those deliberately evading examinations for Tb or [emphasis added] the treatment of Tb, are hospitalized into phthisiological institutions for obligatory examination and treatment by court decisions.” It is stipulated by the same Law that the principle of informed consent is not applicable in this connection and that Tb patients are obliged to undergo prescribed examination and treatment including drug therapy. The nonobservance of this law entails criminal liability. A survey conducted across Russian phthisiological institutions found >6000 legal proceedings in the period 2004-2008 whereas 3163 Tb patients were hospitalized after court decisions [109]. There are administrative and legal mechanisms to hospitalize Tb patients with the help of police and criminal prosecution in case of non-compliance. Among others, the latter pertains to non-contagious Tb patients released from jail [110]. Compulsory treatments are generally at variance with the international practice and regulations. According to the WMA International Code of Medical Ethics, “A physician shall respect a competent patient’s right to accept or refuse treatment.” It was noted in regard to Tb that neither the statutory exceptions to the principle of consent nor the conditions of “required care” allow legally binding measures against patients refusing a treatment or isolation [111]. The informed consent for invasive procedures and chemotherapy is of particular importance in conditions where an overtreatment is not excluded.

Alcoholism

According to official instructions, indications for surgery were
more frequent in alcoholics than in other Tb patients [112]. In case of alcoholism, the surgical treatment was recommended to be implemented earlier, after a shorter period of medical therapy [85]. Perelman et al. stressed the importance of early surgical treatment of Tb patients with alcohol dependence, and operated them also in the absence of demonstrable microbacteria (e.g. 41 cavernous, 49 tuberculoma cases; M. tuberculosis detected in 55 out of 90 patients). At the same time, they noticed that alcoholics have more post-surgery complications than other patients [113]. Bronchoscopy was applied in cases with bronchitis [113], which is quite frequent among alcoholics in Russia. Among others, vocal cord injuries were observed after repeated bronchoscopies sometimes performed in conditions of suboptimal procedural quality assurance. It was noticed that vigorous apomorphine-induced vomiting as emetic therapy of alcohol dependence provoked hemoptysis in patients with Tb [114].

Among others, the following treatments were applied to alcoholics: prolonged intravenous infusions, sorbent hemoperfusion, pyrotherapy with sulfozine (oil solution of sulphur for intramuscular injections), endoscopic and surgical biopsies of internal organs, sometimes without clear indications also for research [115-120]. Infusions for the purpose of detoxification were generally recommended for patients with alcoholism including moderately severe withdrawal syndrome: 7-10 infusions/day, sometimes combined with intramuscular or subcutaneous injections. [119-123]. The detoxification therapy was deemed “indicated to almost all alcoholic patients, especially to those with prolonged withdrawal syndrome” [114]. Similar instructions were found in recent monographs [124,125]. Some methods were patented, including infusion therapy and transcerebral electrophoresis of magnesium-containing solutions for the treatment of alcohol withdrawal syndrome [122,126-128]. According to a Cochrane review, there is no sufficient evidence to decide whether or not magnesium is useful for the therapy and prevention of alcohol withdrawal syndrome [129]. Besides, intramuscular injections were recommended: Mg sulfate, glucose, sodium thiosulfate solutions, subcutaneous infusions of saline, extracorporeal ultraviolet irradiation of blood, sorbent hemo- and lymphopherfusion, “cerebrospinal fluid perfusion” or “liquorosorption” [112,115,123,130,131].

The recommended duration of detoxifying treatment including intravenous infusions was 5-10 days, even 10-12 days according to some recommendations [114,115]. This is at variance with the international literature. Alcohol and its metabolites are eliminated spontaneously while rehydration can be usually achieved per os. It should be stressed that lengthy drip infusions are associated with discomfort. Some alcoholic patients considered such treatments as punishments; this motivation was apparently present in certain medics [132]. In conditions of suboptimal procedural quality assurance, repeated infusions, endovascular and endoscopic manipulations can lead to the transmission of viral hepatitis, which was known to occur in treated alcoholic patients. The combination of viral and alcoholic liver injury is unfavorable. The attitude to alcoholic patients is sometimes less responsible with potentially lower procedural quality assurance. Therefore, indications to intravenous and other invasive manipulations should be thoroughly evaluated.

Reportedly, in 1994 about 60% patients of one of the “phthisiological” institutions for compulsory treatment abscended while a half of them were brought back by the police (militia) [133]. The duration of compulsory treatment in such institutions was around one year or longer [114]. The compulsory treatment was endorsed by regulations [114,134]. In 1974, chronic alcoholism was officially declared to be a ground for compulsory treatment; the regulation was made stricter in 1985, making compulsory hospitalization and treatment of chronic alcoholics independent of anti-social behavior. This practice has been designated in 1990 as contradictory to human rights [134]. The system of compulsory treatment of alcoholics was largely dismantled during the 1990s; but some experts recommended its restoration and further development [109]. According to a survey, 62.6% of specialists engaged in addiction medicine (named narcology in Russia) supported compulsory treatment of alcoholism [135].

Discussion

Factors contributing to the persistence of suboptimal practices include a partial isolation from the international scientific community, insufficient use of the foreign literature and unavailability of many internationally used handbooks even in central medical libraries [136]. Thanks to the Internet, the Russian-language literature is increasingly aware of foreign publications, textbooks and guidelines being adjusted to international prototypes. However, some published recommendations have remained without due commentaries, so that a reversion to suboptimal practices is not excluded. The problem has also another aspect. During last decades, numerous former military and other functionaries, their relatives and protégés, have been introduced into educational, scientific and medical institutions. It has further contributed to the persistence of suboptimal and outdated methods in medicine due to lacking professional autonomy [137], autocratic or military managerial style discouraging criticism and impartial polemics. Attributes of this style include the paternalistic approach to patients, insufficient adherence to the principle of informed consent, bossy management, harassment of colleagues if they do not follow instructions in their professional work or not collaborate e.g. in dubious research [138,139]. In conditions of paternalism, misinformation of patients and compulsory treatments were seen as permitted [140]. Suboptimal practices have been used as per instructions by healthcare authorities and leading experts’ publications; numerous examples have been discussed previously [1,2,88,132], to name but a few (apart from those discussed above): electrocoagulation of cervical ectropions without cyto- or histological check for precancerous changes, parabulbar injections of placebo, overuse of bronchoscopy e.g. in conscripts with supposed pneumonia: 1478 procedures in 977 patients [141-143]. Some invasive methods with questionable indications were introduced or advocated by first generation military surgeons [1]. The personnel training could have been one of the motives to overuse invasive procedures. Note that military and medical ethics are not the same. The comparatively short life expectancy in Russia is a strategic advantage as it necessitates less healthcare investments and pensions. Some experts understood obsoleteness of certain instructions, so that personal judgment was involved as well. Actually, Russia needs foreign help in the matters of healthcare. In view of the current international tensions, the cooperation in many areas has been interrupted. Obstacles to the import of medical products, coupled with increasing influence by the military, might have adverse consequences. Domestic products
are promoted despite often lower quality and possible counterfeiting [144]. Military functionaries, their relatives and protégés, will become more dominant thanks to the conflict in the Ukraine. Those participating in the conflict, factually or on paper, will obtain the veteran status and hence privileges over fellow-citizens. War veterans enjoy advantages in the healthcare and everyday life; there are, however, misgivings that the status has been awarded gratuitously to some individuals from the privileged milieu. At the same time, many young relatives of superior officers evaded the mandatory military service under various pretexts. Being not accustomed to hard and meticulous work, some of the functionaries’ relatives have been involved in professional misconduct of different kind [138]. Moreover, sons of superior officers have enjoyed far-reaching impunity in the Soviet and post-Soviet society, becoming inveigled in immoral and illegal activities. High social positions held by perpetrators or their relatives prevented reporting. Admittedly, some problems discussed above are overshadowed these days by migration-related societal transformations [145].

**Conclusion**

Current ethical provisions in Russia are based on the National Standard for Good Clinical Practice [146]. This document is analogous to the Consolidated Guidance for Good Clinical Practice issued by the International Conference on Harmonisation of Technical Requirements for Registration of Pharmaceuticals for Human Use [146,147]. The Standard has been approved by the Federal Agency on Technical Regulation and Metrology (Rosstandart) on 27 September 2005. This is a positive development. However, it is known that the ethical and legal basis of medical practice and research has not been sufficiently known and observed in Russia. The term “deontology” is often used for medical ethics in this country. Textbooks and monographs on deontology explained the matter somewhat vaguely, with truisms and generalities but not much practical guidance. As mentioned above, the professional autonomy and informed consent have not been given sufficient attention. Admittedly, in the field of medical ethics, like in other areas, the Russian literature is being adjusted to foreign prototypes. The relatively new ethical problem is the conflict of interest, vendor relationships, manipulation of patients into paid services etc.; but this is beyond the scope of this review. Today, the growing economy enables acquisition of modern equipment; and medical research is on the increase. Under these circumstances, the purpose of this article was to remind that, performing surgical or medical research is on the increase. Under these circumstances, the risk-to-benefit ratio must be kept as low as possible. Insufficient coordination of medical studies and partial isolation from the international community can result in parallelism in research, unnecessary experimentation, and application of invasive procedures without sufficient indications.
